ABSTRACT

THE EFFECT OF POROSITY ON MECHANICAL PROPERTIES OF FUSED DEPOSITION MANUFACTURED POLYMERS AND COMPOSITES

by Eric H. Anderson

Additive manufacturing has seen sustained growth in both consumer and industrial areas. fused deposition manufacturing (FDM), a specific additive manufacturing technology, has seen increased sales in consumer markets. In order to maintain growth, FDM will be increasingly used for load-bearing applications. However, the mechanical reliability of FDM polymers and composites is not well understood. This can be dangerous to property and safety. Presented in this paper are more than 16 distinct populations comprised of at least 23 unique tensile tests, a total of 506 tensile tests. Weibull statistics were used to quantify variance in physical properties of FDMed materials. It is the hope of the author that these data will provide essential information for designers to make parameter selections for safe load-bearing applications of FDM parts. Using the deviations from Weibull, scanning electron microscopy, and micro X-ray CT, the author examined the origins of variations in mechanical properties. A key factor in mechanical reliability comprises variations in the size and shape of inter-bead pores. In the final section, this problem was addressed with a novel vibration assisted FDM (VA-FDM) that reduced the porosity by 3 %, increased the fracture strength by 12 %, and doubled the tensile strength reliability. These findings showed that inter-bead porosity can be significantly reduced by localized extruder vibrations and that reduced inter-bead porosity influences the mechanical properties and variations in those properties.

ACKNOWLEDGMENTS

I would like to thank Dr. Ozgur Keles for his guidance, encouragement, and patience during this entire thesis process. I would also like to acknowledge the support of Dr. Guna Selvaduray and Dr. Raymond Yee for sharing their knowledge and expertise. A special thank you to Carl Zeiss X-ray Microscopy Inc. and Jeffery Gelb for their assistance in acquiring x-ray μ CT image; as well as the Material Engineering SEM lab at SJSU and Ryan Thompson for their assistance in acquiring SEM fracture surface images. Furthermore, the author would like to thank Briana and Alex Cress for their many sacrifices when resurrecting the 3D printer; as well as Jimmy Huynh's sample testing support and David Loja for sample photographs.

I would also like to thank my family Melissa Loja, Cynthia Anderson and William (Oz) Anderson for instilling the value of science and education from a young age. I am eternally grateful for my family's patience, support, and love. None of this would have been possible without the love and support of my grandparents, Bill and Mugsie Anderson. Finally, I'd like to thank my partner, Briana Squiers, for being the light in my life and giving me the motivation to keep moving forward.

CHAPTER ONE INTRODUCTION

1.1 Significance

Additive manufacturing (AM) is seeing increasing use for applications that require metal, polymer, ceramic, and composite materials [1]. AM provides unprecedented design flexibility, outsource manufacturing, automation, material usage efficiency, and on-demand production, which is reflected in the AM industry's 31.5 % annual growth rate over the last three years and overall growth of 26.2 % in the last 27 [2, 3]. AM has seen growth in many industries, including aerospace [4], medical [5], defense [6], automotive [7], consumer-grade manufacturing [8], dentistry [9], and open-source design [10]. In this context, AM can extend distributed manufacturing—that is, to produce parts locally [3, 11]. AM can be competitive for productions up to 10,000 parts [12]. Accordingly, the variations in mechanical properties must be known to ensure consistent production of parts. However, mechanical strength and reliability of additively manufactured (AMed) composites are unclear. Specifically, stochastic fracture of AMed materials have not been thoroughly investigated. One of the main reasons is the large number of specimens required to obtain statistically significant fracture data.

The major technologies in AM are as follows: selective laser sintering, stereolithographic, polyjet, electronic beam melting, and fused deposition modeling (FDM) [1]. Among these technologies, FDM can use relatively inexpensive materials, making it accessible to industrial and consumer-level production. Commonly used polymers in FDM are acrylonitrile butadiene styrene (ABS), polylactic acid, and acrylate resin and nylon powder [13]. These polymers are affordable and contribute to FDM's

exponential increase in consumer-grade sales [2]. With 140,000 units sold in 2014 and 250,000 units sold in 2015, FDM has become the most used AM technology [2].

Consumer demand shifts FDM printer usage from modeling and prototyping to load-bearing parts [1]. Load-bearing fused deposition manufactured (FDMed) prosthetics [14], medical implants [15], automotive parts [16], and casting manufacturing [17] have been reported.

One advantage of additive manufacturing over traditional subtractive methods is the ability to control internal structure. This flexible production enables spatial control of pores, which can be used to tailor mechanical behavior and reduce weight. Generally, FDMed materials are produced with a fixed porosity described by the infill parameter. However, the direct relationship between porosity and mechanical reliability for FDMed parts is not well understood.

Recent work has shown that FDM produces parts with lower mechanical reliability than their subtractive manufactured counterparts [18]. These part-to-part variations can pose harm to consumers using FDM for load-bearing applications. Reliability is an important design consideration for any load-bearing application but specifically for larger-scale manufacturing.

Porosity can be advantageous for decreasing the weight and material usage of an FDMed part. Tekinalp et al. described two characteristic pores caused by the FDM method: inner-bead and inter-bead pores [19]. Beads, also referred to as “roads,” are the lines of extruded plastic of which FDM parts are composed. Inner-bead pores are described as the pores contained within the bead. Inter-bead pores are described as the

pores that exist between beads. Even at 100 % infill (i.e., nominally dense material), Many FDM studies found significant inter-bead porosity [19]. The rounded beads cannot fill the entire space completely. Inter-bead porosity was reported to decrease with carbon fiber percentage due to higher thermal conductivity and die swell. Inner-bead porosity, however, showed an increase caused by poor fiber-matrix adhesion in FDMed short-carbon-fiber-reinforced polymers [19].

Finding the effects of infill parameter on various mechanical properties FDMed ABS has been an area of interest [20-24]. Fernandez-Vicente et al. compared the tensile strength of open-source FDMed ABS with three different infill patterns [24]. The tensile strength was found to be 16, 20, and 36 MPa, for 20 %, 50 %, and 100 % rectilinear infills, respectively. With five replicates in each infill, the specimens were modeled with a quadratic relationship $\sigma_p \cong 15 * 10^{-3} MPa * x^2$, where σ_p is the tensile strength and x is the infill density.

1.2 Techniques

Analyzing mechanical reliability using Weibull statistics [17] is a common practice in ceramic AM literature [25-28] due to high variability in fracture stress. Although Weibull statistics are not commonly used for polymers, the author recently showed that the variation in FDMed ABS-dense materials can be as high as ceramics [29]. There are currently no reports on the mechanical reliability of AMed short carbon-fiber reinforced acrylonitrile butadiene styrene (SCFR-ABS) composites. In the present study, the author investigated the effect of porosity on the variations in fracture stress (i.e., the effect of porosity on a Weibull modulus).

X-ray microcomputed tomography (X-ray μCT) has been shown to give qualitative results for pores' shape and morphology, a distinct advantage over scanning electron microscopy (SEM), Mercury porosimetry, gas pycnometry, and other imaging techniques [30]. In FDM, X-ray μCT has proven feasible for characterizing the structural features of the roads and the length, width, and orientation of composite fibers [31-34]. The microstructural features and carbon-fiber length, width, and orientation has been shown to be the major contributor in mechanical strength and can be quantitatively determined using micro X-ray μCT techniques[35, 36].

1.3 Motivation

This thesis aims to give an overview of the author's work regarding the stochastic fracture of FDMed ABS and SCFR-ABS. This topic is broken down into three experiments: stochastic fracture of additively manufactured porous ABS (chapter five), stochastic fracture of additively manufactured porous composites (chapter six) [37], and mechanical reliability of short carbon-fiber reinforced ABS produced via vibration-assisted fused deposition modeling (chapter seven) [38]. Chapters six and seven are summaries of published papers [37, 38], of which the author is not the first author. This paper will focus specifically on what the author has contributed to the work while still discussing the findings in meaningful ways.

The results and conclusions reached in this paper can be summarized into three categories: presenting data, investigating causes in the variance of mechanical properties, and addressing the proposed cause. The subsequent paragraphs will suggest to the motivation behind each of these categories.

As mentioned in chapter 1.1, a large data set on the mechanical properties of FDMed ABS and SCFR-ABS is missing literature. This data set gives insight into the degree of variation that can be expected from consumer-grade FDM. It is the hope of this author that these data can be leveraged by slicing software to make parameter selections with the designers' desired load and reliability. In this way, load-bearing applications for FDM parts can be produced safely with significant material knowledge needed by the user. It is the author's belief that this will produce safer parts, mitigate unnecessary material usage, and expand the efficacy of FDM parts.

This paper discusses potential causes of mechanical variation. These conclusions are made after examining Weibull distribution, fractography, and micro X-ray CT data. This discussion alludes to potential causes that should be further investigated. The claims made should not be taken as assertions but as areas of interest. It is the hope of the author that the factors outlined in this paper will lead to further improvements in mechanical reliability.

Finally, this paper will conclude with an experiment on one of the largest factors believed to contribute to mechanical reliability: variations in inter-bead porosity. The author addresses the variations by introducing localized vibrations on the extruder head. Via SEM, the author qualitatively determines a reduction in inter-bead porosity and observes a 12 % increase in tensile strength (TS) and a 200 % reduction in mechanical variability. In this way, the author demonstrates a novel and inexpensive method of increasing the mechanical properties of FDMed materials. It is hoped that this will increase the efficacy of FDM printing for load-bearing applications.

CHAPTER TWO LITERATURE REVIEW

Weibull analysis of varying porosities of FDM SCFR-ABS is novel. It combines the approach, manufacturing, and material of a system never reported on before. The major findings in FDM SCFR-ABS, the effect of infill on mechanical properties, and Weibull statistics are discussed in this section. The author uses these findings as a basis to discuss the effects of porosity on the reliability of FDMed SCFR-ABS.

2.1 SCFR-ABS FDM Literature

SCFR-ABS is a desired material for FDM for its improved density, toughness, and mechanical, electrical, and thermal properties [39-41]. Although studied in the extrusion compounding and injection-molding processes [42-44], SCFR-ABS has not been highly studied for FDM. Mechanical properties have been shown to significantly depend on the porosity, fiber-length distribution, and fiber-orientation distribution of the final parts.

Ning et al. correlated carbon-fiber length with higher ultimate tensile stress, which explains major differences between the values of Tekinalp et al. and Ning et al. However, when comparing the 10 wt. % of Shofner and Ning et al., it is seen that variation in processing can cause significant differences in reported stress for the same carbon-fiber length. Ning et al. and Shofner et al. tested five and six replicates, respectively.

The remainder of this section will focus on the work of Tekinalp et al. due to its focus on the three factors that affect mechanical reliability: fiber length, fiber orientation, and porosity. By changing the infill percentage, the inter-pore percentage (which has been defined in this paper) changes directly. The effects of FDM on fiber length and fiber orientation are also widely discussed in this paper.

2.1.1 Highly Oriented Carbon Fiber-Polymer Composites via AM [19]

In the work of Tekinalp et al. on highly oriented carbon-fiber polymer composites, the microstructural and mechanical properties were compared for FDM and compression-molded (CM) techniques. The microstructure analysis depicted two pore vacancies for FDM modes that were shown to have dependence on carbon-fiber concentration. The tensile strength and modules showed an increase of 115 % and 700 %, respectively. A fiber alignment of 91.5 % was achieved using FDM printing, significantly higher than compression-modeling techniques.

2.1.2 Methods

Mixtures of 0 %, 10 %, 20 %, 30 %, and 40 % SCFR-ABS were created using a Brabender Intelli-Torque Pliati-Corder prep mixer at 220° C. A slit-shaped and cylindrical die was used for CM and FDM, respectively. The American Society of Testing Materials (ASTM) D638 dog-bones were created using the FDM printer Solidoodle 3 (from Solidoodle Co., New York).

2.1.3 Porosity

Tekinalp et al. compared the microstructure of raw ABS with that of composite FDMed and found two types of porosity. Inter-bead porosity features triangular pores that are byproducts of FDM printing. When the nozzle prints against a surface, the filament flattens and elongates while the top side cools to form rounded edges before the next layer is deposited. The triangular pores are not expected to have a significant effect on the mechanical properties because the pore channels are aligned with the tensile test direction. It is important to note that in this experiment, the infill angle (hatch angle) of

the infill roads was set to 0° for all layers. For nonzero hatch angles, the pore channel is not aligned with the tensile direction and has been shown to produce much weaker specimens [45].

There was a significant reduction in inter-bead porosity with the addition of carbon fibers. Carbon fiber significantly eliminates die-swell and improves the thermal conductivity, causing bead softening and smaller bead size. This reduction is one of the causes for the increase in specific strength and specific modulus, as shown in Figure 1.

Figure 1. Depicts the relationship of carbon fiber on inner-bead and inter-bead formation as well as the specific strength and modulus. Adopted from H.L. Tekinalp et. al. [19].

Inner-bead pores are caused by increasing fiber ends [19]. SEM shows pore enlargement around the fibers for the FDM but not for the CM samples. This enlargement

by FDM printing lowered the fiber-matrix interfacial contact area and was expected to reduce strength.

2.1.4 Fiber-Length Distribution

To access fiber length, a major contributor to mechanical strength, the ABS in the samples was dissolved with acetone. Micrographs of 1,000 carbon fibers were taken at 20x zoom. Code was then developed to determine the fiber-length distribution.

The fiber-length distribution for CM and FDM both decrease with increasing weight percentages. Even though 3.2 mm-long fibers were used during processing, the average fiber length for both AM and CM processes was found to be lower than 0.4 mm. This suggests significant fiber breakage during the processing steps. Previous research has shown that the leading causes of fiber breakage during processing are interactions with the fiber and the instrument surface, resin, and other fibers [19]. As the carbon percentages increase, these fiber interactions cause increased fiber breakage, thus lowering fiber length.

2.1.5 Fiber Orientating

To determine fiber orientation, the Bay and Tucker fiber-orientation methodology was used. This method consists of imaging a polished internal surface and using fiber surface morphology to determine second-order fiber orientation.

The results of Bay and Tucker's method was a high fiber orientation in the raster direction for FDM, compared to CM methods. With 90 % of the fiber printing in the raster direction, FDM is a strong manufacturing technique for aligning carbon fibers. In

this study, the raster direction is the most mechanically favorable orientation because it is in the load-bearing direction.

2.1.6 Tensile Testing

As previously mentioned, this study focuses on the fiber length, fiber orientation, and porosity of SCFR-ABS. It has previously been shown that tensile strength increases with fiber length and orientation and decreases with increasing porosity. Despite the voids created by FDM, neat ABS showed higher tensile strength than CM methods. This suggests that the molecular orientation is improved with FDM methods [19]. The tensile strength and modulus showed a general increase in carbon fiber percentage for both FDM and CM methodologies.

At least five specimens were tested in each test case, and standard deviations were calculated. FDM showed a significantly lower standard deviation than CM. This suggests that the FDM method not only increases the orientation of the fibers, but also increases the dispersion of fibers compared to CM. The standard deviation of neat polymers is higher than that of the carbon fiber; this suggests sample-to-sample differences in carbon-fiber dispersion.

2.1.7 Conclusion

Varying carbon-fiber weight percentages were manufactured using FDM and CM methodologies. The three largest contributors to mechanical strength, fiber length, fiber orientation, and porosity were studied. Fiber length was measured using micrograph techniques and determined similar carbon-fiber-length averages between FDM and CM. In both techniques, significant fiber breakage was observed. Fiber orientation was

observed using the Bay and Tucker [46] polished-surface 2-D ellipsoid method. A significant increase in the carbon-fiber orientation was observed. No porosity was observed in the CM models, but significant porosity was observed in the FDM samples. The pores that arose from gaps in between pores the were termed “inter-bead pores”. The pores within the beads were termed “inner-bead pores”. Via SEM, it was determined that the inter-bead pores decreased with carbon-fiber concentration, but the number of inner-bead pores increased.

Tensile test methods showed increasing tensile strength and modulus with increasing carbon-fiber weight percentages. Based upon the standard deviations of a five-sample minimum, it was determined that there was better dispersion of the carbon fiber in the FDM methodology. The strength of neat ABS was higher in FDM compared to CM methodologies. This suggests an alignment of the polymer chains in the ABS process as described by Sood et al. [47]. Carbon fibers were seen by SEM to be pulled out of the matrix. This suggests weak interfacial adhesion between the fiber and the matrix. Tekinalp et al. suggested improving the interface between fiber and matrix for the largest improvement in mechanical properties [19].

2.2 Infill Variations

Very few papers have been published that examine infill effect on mechanical properties. Baich and Manogharan analyzed print cost and time based on infill percentages using a slicing software that does not allow the fine-tuning of infill percentages. In this study, the focus will be on the paper of Fernandez-Vicente et al. as it

specifically addresses varying infill and patterns and percentages for RepRap printers.

2.2.1 Effect of Infill Parameters on Tensile Mechanical Behavior in Desktop Printing

In the work of Fernandez-Vicente et al. [26], five replicate-FDMed pure ABS samples were tested at infills of 20 %, 50 %, and 100 %. The tensile strengths were found to be 15.62, 19.58, and 36.40 MPa, for 20 %, 50 %, and 100 % infills, respectively. The specimens were modeled with a quadratic relationship and are shown in Equation 1.

$$\sigma_p = 15.2364 \text{ MPa} + .002083 * x^2 \quad \text{Equation 1}$$

Where σ_p is the tensile strength, and x is the infill density.

2.2.2. Methods

The three infill patterns studies in this paper are rectilinear, honeycomb, and line, with 20 %, 50 %, and 100 % infill parameters. These patterns were created on the slic4r version 1.0 and printed on the RepRap Prusa i3.

2.2.3 Tensile Results

The tensile strengths of the rectilinear model were found to be 15.62, 19.58, and 36.40 MPa for the 20 %, 50 %, and 100 % infills, respectively. As expected, the 20 % infill parameter was the weakest out of the three infill patterns; while, the 100 % parameter was found to be the strongest of the three. This is particularly interesting because the 100 % infill parameter was also the lightest of the three specimens. The authors hypothesized that the difference may be related to inter-bead interactions, of which the rectilinear model has the most.

2.2.4 Conclusion

The maximum tensile strength found in this paper was a 100 % infill, which shows a 36.4 MPa—a difference of 1 % of raw ABS material. The difference in elastic modulus

between the honeycomb and the rectilinear pattern is due to the deposition trajectories and the interlayer bonding zones. Finally, the relationship between infill density and tensile strength can be fitted in a squared-X model.

CHAPTER THREE OBJECTIVE

This paper covers three topics on which the author has worked extensively: stochastic fracture of additively manufactured porous ABS (chapter five); stochastic fracture of additively manufactured porous composites (chapter six) [37]; and mechanical reliability of short carbon-fiber reinforced ABS produced via vibration-assisted fused deposition modeling (chapter seven) [38]. The broad goal of these three papers is to understand the variability of FDMed materials. This goal can be divided into three components: providing a data set that is not present in literature, listing novel suggestions on improving reliability, and experimentally improving reliability based on suggestions. Experiments from chapters five and six will provide data sets and suggestions for improving reliability. In chapter seven, the author shows improvement in mechanical reliability by addressing one of the suggested sources.

CHAPTER FOUR MATERIALS AND METHODS

In this chapter, the necessary materials and methods are described. This section will cover all testing that is similar between the ABS, SCFR-ABS, and VA SCFR-ABS experiments. Experimental methodologies specific to the individual experiments will be located in the papers' respective chapters (ABS—chapter 5.2; SCFR-ABS—chapter 6.2; VA-FDM—chapter 7.2).

The Instron 4204 Universal Tester was used to perform and record tensile test data. The FEI Quanta 200 took the SEM images. The Prusa i3 3-D printer was the open-source FDM printer used. The Instron 4204 Universal Tester and FEI Quanta are available to students in the material engineering department. The Prusa i3 3-D printer is the property of Dr. Ozgur Keles's research lab, to which the author belongs.

4.1 Manufacturing

The tensile test specimen was modeled from a modified ASTM D638 Type 1 standard using SolidWorks 2016 computer-aided design software. The modification is necessary because the curvature of the dog-bone sample causes defects and fractures in invalid test areas [48]. The curvature was removed to form a rectangular box with a length of 165 mm, a width of 13 mm, and a height of 3.6 mm.

A stereolithographic file (STL) was then created using SolidWorks with the maximum polygon count allotted. Ten identical models were made and oriented using the open-source software suit Repetier-Host (version 1.6.2). The G-code, numerical control programming language, for the 10 models was created using Repetier-Host's built-in

plug-in, Slic3r. The printing parameters used in generating the G-code are described in Table 1.

Table 1 Slicing Parameters Used to Create G-code.

Print Parameters	Value
Cross head speed (mm/min)	7800
Raster Orientation (Deg)	45/ -45
Perimeter Overlap (% of extruded perimeter width)	15
Bed Temperature (Celsius)	125
Nozzle Temperature (Celsius)	235
Layer Thickness	.3 mm
Number of parameters	1
X-Y deposition speed (mm/min)	4800
Fill density	20, 40, 60, 80 and 100%
Filament diameter	1.75 mm
Nozzle diameter	.6 mm

Five variations of these files were created with varying infill percentages: 20 %, 40 %, 60 %, 80 %, and 100 %. The top and bottom two layers were set to solid infill to ensure level grip area and isotropic grip stress distribution. Four batches of 10 were printed for each infill percentage to ensure 30 samples for the Weibull analysis.

Adhesion is a common difficulty in FDM. As the manufacturing progresses, thermal contraction causes the part to delaminate. To address this, a thin layer of ABS dissolved in commercial grade acetone was used. A thin layer was dispersed with a painter's brush; this layer needed to be reapplied after every batch. Batches of 10 samples took two to five hours, depending on infill, and were often left to run unattended. Any unexpected

variations occurring during unattended printing are characteristic of real processing conditions.

4.2 Strength Testing and Characterization

Tensile tests were conducted on printed specimens using an Instron 4204 Universal Tester with Bluehill 3 data-analysis software at a strain rate of 1 mm/min. A static axial clip-on extensometer provided gauge strain. Length, width, thickness, and weight measurements were made on all samples' density, strain, and geometric changes from the printer.

An FEI Quanta 200 scanning electron microscope was used to measure fracture surface. Gold/palladium alloy sputtering was required to image the fracture surface of ABS samples but was not needed for carbon-fiber samples.

4.3 Weibull Analysis

Mechanical reliability, or variations in fracture strength, is commonly quantified by the two-parameter Weibull distribution [49].

$$F(\sigma, V) = 1 - \exp \left[-\frac{V}{V_0} \left(\frac{\sigma}{\sigma_0} \right)^m \right] \quad \text{Equation 2}$$

Where the probability of failure (F) is related to the volume (V) and applied stress (σ).

The Weibull modulus (m) is the shape parameter. Higher m results in less variation in strength. The scale parameter (σ_0) or characteristic strength corresponds to the failure probability of 63 %. The volumes of test specimens in each batch, and from batch to batch, do not differ significantly from the normalized volume (V_0); thus, the author sets

$\frac{V}{V_0} = 1$. Performing a two-parameter Weibull analysis on tensile test data gives the

probability of failure at a given stress or strain value—essential for designing the load-bearing parts safely.

Apart from the previous work, the only paper to analyze additively manufactured material using Weibull statistics is that of Meininger et al. [50]. This 2016 work uses a three-dimensional powder printing technique to create strontium substituted magnesium phosphate scaffolds for the purpose of in vitro bone cement. Meininger et al. calculated the Weibull moduli for varying sintered and hardened methods for three different magnesium strontium phosphate mixtures. They also showed that the $Mg_2Sr_1(PO_4)_2$ scaffolds had the highest Weibull modulus of $m_{cs} = 8.8$ and therefore were the most reliable under compression [50].

4.4 Safety

The AM material SCFR-ABS is the main material used in this experiment. The print head is operated 235° C and can cause burns with direct contact. To relieve burns, it is advised to soak under water for 15 minutes. If skin irritation persists, one is instructed to call a doctor. It does not self-ignite and decomposes at 508° C, so it is important to check to see that the printer is working at measured temperatures. Inhalation of ABS particles can be harmful to health, so it is advised to avoid sanding or creating fine particles. If exposed, one should move to fresh air and consult a physician.

Acetone is used to dissolve the SCFR-ABS, which is then used as an adhesive used during printing. Acetone is an irritant; for skin exposure the area should be flushed with lukewarm, gently flowing water for 5 minutes, and 15 to 20 minutes for eye exposure. If

skin contact is serious, one should use disinfectant soap and cover contaminated skin with an antibacterial cream. In all scenarios, medical attention is needed.

Acetone is flammable with an auto-ignition of 465° C and a flash point of -20° and -4° C for a closed and open cup, respectively. Chemicals should be stored in a fire cabinet. To combat fire, one should use dry chemical powder, alcohol resistant foam, water spray, or fog. A summary of the safety information regarding SCFR-ABS and acetone is shown in Table 2.

Table 2 Safety Information

Chemical	Health	Flammability	Reactivity	Personal Protective Equipment	Other
SCFR-ABS	0	1	0	Eye protection	
Acetone	1	3	0	Gloves, lab coat, vapor respirator	

CHAPTER FIVE

STOCHASTIC FRACTURE OF ADDITIVELY MANUFACTURED POROUS ABS

In this chapter, the author measures the effect of porosity on the mechanical properties of FDMed ABS. The variance in mechanical properties is described using Weibull statistics, as related in chapter four. In this way, the author can imply the root causes' of variation and mechanical properties. The following section will present the mechanical properties of five different populations of porosities. To generate samples of varying porosities, the infill percentages of 20 %, 40 %, 60 %, 80 %, and 100 % were used. The infill parameter changes the degree of inter-bead porosity. In this way, researchers can directly see the effect of inter-bead porosity on mechanical properties and mechanical reliability.

In this chapter, more than 300 tensile tests will be presented. This large data set can be leveraged by slicing software to make informed parameter selections. Ideally, a user would simply need to specify a tensile load and desired reliability, and the software would make the appropriate selection.

5.1 Introduction

With more than 300 samples printed and tested, this study is the largest of its kind. Reliability will be determined for five infill percentages: 20 %, 40 %, 60 %, 80 %, and 100 %. It will provide programmers, designers, and consumers with information they can use to design load-bearing parts safely. The effect of inter-bead porosity on reliability and other mechanical properties will be examined.

5.2 Materials and Method

Octave Inc. acrylonitrile-butadiene-styrene polymer filament was used on a RoaddogLabs Baja i3 rework to print all tensile test specimens. Due to the difficulties of breaking at the tensile test grip, the contours of an ASTM D638 were removed to form a rectangular box of the following dimensions: 165 x 13 x 3.6 mm. The open software Slic3r (version 1.2.9, Slic3r (n.d.)), was used to create the toolpath of the FDM. Each tensile test specimen consisted of 12 layers. To minimize the effect of surface defects on the mechanical properties of the specimen, the top two and bottom two were kept at 100 % infill, while layers 3–10 had variable infill percentages at 20 %, 40 %, 60 %, and 100 %. A rectilinear fill pattern was used with a single contour. A 0.4 mm nozzle extruded filament at 235° C onto a 125° C bed.

5.3 Results and Discussion

The consolidation of fracture points for all tensile tests is plotted in Figure 2. As expected, there is a clear separation in the fracture stress and Young's modulus of the different infill percentages. Between 20 %, 40 %, 60 %, and 80 % infill, average tensile strength increases at a rate of 17 %. However, between 80 % and 100 %, there is a 30 % increase in tensile strength. This is exemplified in Figure 2b, with the 100 % infill red data points significantly out of the range of the linear fit of infill percentages 20 %, 40 %, 60 %, and 80 %. This implies that there is a further strengthening in the 100 % infill parameter that cannot be explained by the increase in density alone.

Figure 2. FDMed tensile test specimens at 20 % (green), 40 % (purple), 60 % (orange), 80 % (blue), and 100 % (red) infill. The point of fracture for each test is marked with an x . A) A single stress-strain plot is shown for each infill percentage, showing characteristic stress-strain behavior. Dips near the 4 % strain are a pause in the test for the removal of the extensometer. B) Density vs. tensile strength of each infill percentage. The black dashed line is a linear fit of the 20 %, 40 %, 60 %, and 80 % infill data points, with an equation of $y = 28.11x - 2.64$, $R^2 = .94$.

One possible explanation for this increase in tensile strength is the physical touching from bead to bead. As hot beads are extruded next to each other, the beads merge into a homogeneous material. This can be seen in Figure 3, comparing the fracture surfaces of the 100 % and 40 % infills. The bead to bead interface in the 100% infill increases the fracture surface for an individual bead. The crack must propagate along the length of the bead as well as perpendicular to the bead. This increased fracture area leads to increased toughening as the crack travels longer under similar stress.

Figure 3. Fracture surface of 100 % infill (left) and 40 % infill (right) by SEM. For two beads, the fracture surface is highlighted in blue, with the remainder of the bead highlighted in red.

Looking at the distribution of fracture points in Figure 2, 80 % (blue) shows a much higher distribution in fracture stress than other infill percentages. This can be seen in the linearized Weibull plot shown in Figure 4. The slope of the line, or Weibull parameter m , is highest for 80 % infill. According to these data, 80 % infill has the lowest reliability of all the infills. The reliability of the 80 % infill seems to be correlated to the large distribution of density, as shown in Figure 2b.

Figure 4. Weibull distribution of 20 % (green circle), 40 % (purple x), 60 % (orange diamond), 80 % (blue +), and 100 % (red circle) infill percentages. A) Fracture stress, B) tensile strength, C) strain at break, and D) strain at tensile strength are shown.

The linearized Weibull distribution is shown in Figure 4. The dotted lines represent the linearized Weibull distribution. The slopes of the line (the Weibull modulus m) represent the variation in tensile stress or strain for each infill percentage. With the exclusion of the 80 % infill, there was not a statistically significant difference between infill percentages for σ_f and TS. The 80 % infill showed an $m = 14$ for σ_f and $m = 13$ for TS, whereas the other infills ranged from $m=24-39$ for σ_f and $m = 24-40$ for TS. These low m values mean a large scatter in σ_f and TS values.

Like past results [29, 37, 38], the strain values show lower m values compared to strength values. The ϵ_f showed an increasing trend with increasing density. The 100 % infill showed the lowest ϵ_{TS} of 3.1 %, breaking the trend of increasing ϵ_{TS} with infill percentage.

In our previous study, we reported similar m_f and m_{TS} values for short carbon-fiber composite samples at the same infill parameter settings [18, 37, 38]. The short carbon-fiber ABS results gave an m value range of 19–40 for fracture stress, whereas the clean ABS results showed a similar distribution of $m = 14$ –39. A previous study on a Stratsys uPrint showed a fracture stress range of $m = 46$ –67. This suggests that the Stratsys uPrint produces more reliable samples than the inexpensive RoaddogLabs Prusa i3 Baja rework.

The strain at fracture m value was much lower than previous carbon-fiber composite results. This would correlate with the idea that composite samples fracture in a brittle manner compared to the clean ABS's more ductile fracture. It can be seen from Figure 2 that as density increases, the stress strain shows an increasingly plastic behavior. This would explain the 80 % and 100 % infills' very inconsistent strain-at-fracture values.

Table 3 Summary of Results from FDMed ABS Study

Infill	Fracture Stress (σ_f)		Tensile Strength (σ_{TS})		Strain at Fracture(ϵ_f)		Strain at Tensile Strength (ϵ_{TS})	
	m	S_o	m	S_o	m	S_o	m	S_o
20%	24	12.7	24	13.1	7	4.0	8	3.5
40%	39	15.4	39	15.7	15	5.3	17	4.7
60%	33	18.8	34	19.0	10	5.3	14	4.8
80%	14	22.6	13	23.0	5	6.4	9	5.4
100%	34	30.6	40	33.3	5	7.1	9	3.1

Along the side of the tensile test coupon, a periodic crazing pattern can be seen. This is shown with the 20 %-infill specimen in Figure 5. The infill pattern generated by Slic3r produces regions in which the infill runs along the perimeter and portions in which it does not. This is clearly shown in Figure 5C, where a large weld can be seen running along the perimeter of the part and white crazing where the infill does not run along the perimeter. Figure 5A shows a computer-generated depiction of the infill pattern where the portions in which the infill does not run along the perimeter are highlighted in red. The red portions correlate closely with the periodic crazing seen along the side of the tensile test specimen.

Figure 5. a) A visualization of the G-code for the 20 % infill pattern. Areas where the infill does not run parallel with the parameter is highlighted in red. b) A side profile of a broken 20 % infill tensile test coupon. Periodic crazing can be seen along the side of the sample. c) An only-20 %-infill specimen was printed and tensile tested. Crazing is shown in the portion where the infill does not run parallel with the perimeter.

5.4 Conclusion

In this chapter, the mechanical properties of five data sets of varying porosities are given. These values, summarized in Table 3, can be used by slicing software to make intelligent design choices, producing parts at higher safety and efficacy for users and designers. A deviation from a linear change is shown with the 100 % infill parameter.

This suggests a strengthening mechanism that deviates from the strengthening caused by a reduction in porosity. The author suggests that the strengthening is caused by the fusing of two neighboring beads. Finally, significant crazing patterns were shown in defined locations on the tensile specimens. This suggests that the infill pattern localizes stress on the single perimeter surface and that shifting layers could distribute the load through a larger portion of the material and increase strength and reliability.

CHAPTER SIX

STOCHASTIC FRACTURE OF ADDITIVELY MANUFACTURED POROUS COMPOSITES

This section presents a reproduction of the experiment from the previous section with SCFR-ABS. One way to address the mechanical property deficiencies of FDMed ABS is to include continuous or short fibers. This has been shown to improve mechanical properties over clean ABS; however, it has shown problems of nozzle wear and increased inner-bead porosity [19].

In this study, the author used 3DXTech SCFR-ABS feedstock. Unlike other FDM composite literature, the researchers do not make their own composite material [19, 51-53] because they wish to give a representation of the mechanical properties of consumer-grade material produced by a consumer-grade printer. One side effect is a more porous feedstock than in related studies. This commercial composite feedstock not only produced parts with lower σ_f values than literature but has also reduced mechanical properties, compared to the clean ABS results presented in chapter five. This would not be the case with a denser filament; however, to this author's knowledge, no such filament is commercially available.

6.1 Introduction

FDMed ABS material shows reduced mechanical properties compared to injection molding [48]. One common way to address the mechanical deficiencies of FDMed ABS is to composite the material with short carbon fibers [19, 53-55], continuous fibers [56, 57], graphite [52], and graphene [58]. Of these reinforcing agents, short carbon fiber is the most studied. Effects of processing parameter, carbon-fiber content, fiber length, and

raster orientation have been reported for FDMed SCFR-ABS [19, 51-55]. These studies, however, were performed with a sample size ranging from 5 to 12, which is not statistically significant enough to investigate the stochastic fracture of FDMed SCFR-ABS. A large sample set ($N > 20$) is required to estimate the mechanical properties with low relative error [59]. The scatter of Weibull moduli drastically decreases as the sample sizes exceeds 20; however, the diminishing returns as the sample size approaches 40. For instance, the relative layer decreases by 4 % from 27 to 40 but only decreases 5 % from 40 to 80 [59].

In this section, researchers investigate the effect of porosity and raster orientation on the stochastic fracture of FDMed SCFR-ABS. Five porosity levels between 13 % and 53 % by volume were tested. Each test cell contained a minimum of 27 specimens per bath for a total of 241 tests. The filament was also tested as received, for a total of 90 tests. The short carbon-fiber filament has a brittle behavior under tensile load. Therefore, Weibull statistics were used to quantify variations of the mechanical properties.

Experimental strength data were used to set up micro-mechanical strength-simulation framework, which revealed the origin of variation in mechanical properties. Fractography was performed using an electron-scanning microscope (SEM), and x-ray microscopy was used to access the variations in pores in FDMed composites.

6.2 Materials and Methods

Two sets of filaments were bought from 3DXTech (Michigan, US). These sets are called material 1 (M1) and material 2 (M2). M1 was purchased one year before M2. This

study repeated the 20 %, 40 %, 60 %, 80 %, and 100 % infill test cells; however, it introduces a 0° raster orientation.

A theoretical density of 1.08 g/cm³ was calculated using 6.5 % carbon fiber (obtained by micro x-ray CT analysis). Using this theoretical density and taking the mass and volume of the tensile pieces, porosity was calculated using the following Equation 3:

$$Porosity (\%) = \frac{1.08 \frac{g}{cm^3} - Measured\ Density}{1.08 \frac{g}{cm^3}} \quad \text{Equation 3}$$

Thirty tensile tests were produced for the filament as received for M1 and M2, and extruded M1 filament. Samples that broke at the grips were not included in the population; therefore, a total of 90 valid samples are reported.

Two-cm segments of M1 filament were taken before and after extrusion and left to dissolve in 10mL of reagent-grade acetone. The solution was then pipetted onto a glass slide for viewing in an Olympus SZX10 Stereo Microscope at 20x magnification. ImageJ2 [60] software was used to digitally measure the length of ~200 carbon fibers.

The ZEISS Xradia 410 Versa x-ray microscope was used for the 3-D data acquisition [35, 36]. Two-dimensional (2-D) x-ray radiographs were automatically collected across uniformly spaced angular positions and composited into a 3-D model using ZEISS XMReconstructor software [61]. Approximately 1,600 radiographs with dwell times of 10 to 15 seconds were taken. The total acquisition and reconstruction times were 5–7 hours for each sample. Three phases were identified in the constructions: polymer matrix, carbon fiber, and pores.

6.3 Results and Discussion

Five different sources of pores were discovered from the digital images and x-ray computed tomography (Figure 6, Figure 7). These pore sources are: a) designed porosity for infill $< 100\%$; b) inter-bead porosity due to the lack of complete geometric filling between beads; c) inner-bead porosity inherited from the as-received filament; d) inner-bead porosity due to flow incompatibility between ABS and carbon fiber; and e) inner-bead porosity due to pores generated during high-temperature extrusion. The inter-bead porosity was controlled by adjusting the infill percentage in the slicing program. The infill percentage dictates the attempted spacing in between beads, with 100% infill denoting that the beads are touching. A 100% infill represents a nominally dense material, while a $< 100\%$ infill represents a rectilinear lattice structure. Examples of 20% and 80% infill are given in Figures 6a and 6b. These intentional pores are the largest pores in FDMed composites.

Figure 6. Photographs of internal structure of: a) 20% ; b) 80% ; c) a representational subsection of the 80% microstructure; d) simulated 80% infill structure. Adopted from O. Keles et. al. [37].

Figure 7. X-ray computed tomography of a) 100 % infill of FDMed SCFR ABS (inter-bead pores are highlighted in red); b) 100 % infill showing inner-bead pores and inter-bead pores highlighted in red; c) images showing a porous interface between carbon fibers and ABS matrix; d) image of SCFR-ABS as feedstock as-received; d1) cross-section plane of the filament, showing a porous core; d2) images of pores at the carbon-fiber ABS interface in the as-received feedstock; e) extruded filament into air (gray denotes the ABS matrix, red the fibers, and green the pores); f) extruded bead onto a heated bed. Adopted from O. Keles et. al. [37].

Despite being set to 100 % infill, the circular nozzle cannot fully complete the volume of the desired part. This is exemplified in Figures 7a and 7b. The inter-bead porosity can be reduced by deposition path algorithms [62], using a thermally expandable second-phase in filament [63], and by over-extruding to fill inter-bead pores at an infill percentage higher than 100 %. In this study, no attempt was used to reduce the inter-bead porosity at 100 %. Therefore, the inter-bead pores are the largest pores in the 100 % infill. Inter-bead pores form triangulated pores that run the length of the neighboring bead's deposition. The widths and shapes of these pores are variable, dictated by nozzle

size, layer thickness, and extrusion temperature. The total porosity for the 100 % infill sample was 15 % by volume for M1 and 13 % for M2. If one subtracts the inherited ~5 % porosity by volume of the extruded filament, then one can roughly estimate that 8 %–10 % of the fully dense material is comprised of inter-bead pores.

The author observed large Figure 7b and small Figure 7c inner-bead porosity. Large inner-bead pores ($>50\ \mu m$) were inherited from the as-received filament (Figure 7d1). The x-ray μ CT reconstruction shows that the filament contained ~5 % porosity by volume. These pores were entrapped during the deposition and printed along with the carbon fibers. The sphere-like pores in the as-received filament became elongated during extrusion (Figures 7e and 7d). Small pores at the fiber ends were also present in the filament before (Figure 7d2) and after (Figure 7c) extrusion. Small pores at the fiber ends are caused by flow mismatch between the fibers and ABS [19]. Increasing the nozzle temperature from 200 °C to 240 °C has been previously reported to increase the inter-bead porosity in SCFR-ABS [52]. Researchers use the material supplier's (3DXTech's) recommended nozzle temperature of 235 °C. This high temperature could have caused higher inner-bead porosity. The relative ratios of inner-bead between porosity inherited from the filament, pores at the fiber ends, and pores generated from the high thermal expansion are challenging to quantify.

The extrusion of the as-received filament increased its porosity from 5 vol. % to ~20 % for air extrusion and ~22 vol. % for deposition on the hot printed bed. These values were obtained by x-ray CT data and are larger than the 13 %–15 % of the total porosity of the 100 % infill samples. This is caused by a reduction in porosity as the print head

moves away from the heated bed (Figure 7e). There was fluctuating porosity from the as-received filament (Figure 7e). In the remainder of the discussion, “porosity” refers to total porosity.

Tensile tests were conducted on seven populations of FDMed SCFR-ABS, containing a minimum of 27 replicates. The total number of tensile tests conducted was 241. This information is summarized in Table 4. The nominally dense sample had 100 % infill and average fracture stress (σ_f). As the porosity increased, σ_f and TS decreased (Figure 8). The effects of infill percentage on the TS of FDMed ABS have been reported by Fernandez-Vincente et al. [24]. In that ABS study, the TS of the 20 %, 50 %, and 100 % infills were reported to 16, 20, and 36 MPa for the 20 %, 50 %, and 100 % infills, respectively. These TS data fit the function $\sigma_p \cong 15 + .002x^2$, where σ_p is the TS and x is the density. The researchers fit the same function to the FDMed SCFR-ABS and obtained a $\sigma_p \cong 11 + .001x^2$ with an $R^2 = 0.99$. The SCFR ABS showed a lower dependence on infill than the ABS. This is due to a higher volume percent of inner-bead (Figures 9b and 9c) pores and the larger inter-bead pores (Figure 9a) created by the larger composite nozzle.

Table 4 Summary of Results from FD Med SCFR-ABS Study

M	P (%)	E (GPa)	σ_f (MPa)		TS (MPa)		ϵ_f (%)		ϵ_{TS} (%)	
			m	σ_o	m	σ_o	m	σ_o	m	σ_o
1	15 $\pm$ 4	2.5 $\pm$.01	24 (19-30)	23	23 (18-29)	23	11 (9-14)	3.7	28 (22-36)	3
1	25 $\pm$ 3	2.1 $\pm$.01	25 (20-30)	20	24 (20-30)	20	21 (17-26)	3.2	26 (21-32)	2.9
1	34 $\pm$ 2	1.9 $\pm$.009	18 (15-21)	16	18 (15-21)	16	15 (12-19)	2.4	18 (15-22)	2.3
1	41 $\pm$ 1	1.7 $\pm$.008	36 (30-44)	13	41 (34-49)	13	11 (9-14)	2.3	12 (10-15)	2.3
1	53 $\pm$ 1	1.5 $\pm$.008	39 (32-48)	11	41 (33-51)	11	8 (7-10)	1.9	9 (7-11)	1.8
2	23 $\pm$ 3	5.0 $\pm$.004	40 (35-52)	32	46 (36-61)	33	17 (13-22)	2.4	19 (14-25)	2
2	13 $\pm$ 3	3.0 $\pm$.003	19 (15-24)	24	19 (15-25)	24	9 (8-12)	2.8	8 (6-10)	2.7

Figure 8. Effect of porosity on the average fracture strength of FDMed SCFR-ABS. The symbol Δ represents M1, and $\blacktriangle$ represents M2. The symbol $\blacktriangledown$ represents M2 with 0° bead orientation. The dotted trendline represents a fit of the form $\sigma_0 \text{Exp}[-bP]$ ($\sigma_0 = 30 \text{ MPa}$, $b = 0.02$) with an $R^2 = 0.99$. Error bars represent one standard deviation. Adopted from O. Keles et. al. [37].

Figure 9. SEM micrographs of the fracture surface of the nominally dense 10 % infill, including photos of a) inter-bead porosity; b) fiber pores; and c) inner-bead porosity. Scale bars correspond to 1mm, 200 μm and c) 20 μm . Adopted from O. Keles et. al. [37].

The FDMed SCFR-ABS tested showed a brittle fracture behavior with little plasticity. The difference between the tensile behavior between ABS and SCFR-ABS can be attributed to strong pore-to-pore interactions within inner-bead pores. The most porous samples (52, 40, and 31 vol. %) showed to be the most brittle samples, with statistically identical ϵ_{TS} and ϵ_f (Table 4). The denser samples showed limited plasticity of 4.5 % between ϵ_{TS} and ϵ_f . Therefore, the researchers commonly use Equation 4 to describe the relationship between σ_f and Porosity (P) for brittle systems (Figure 8) [64, 65]. In this expression, b represents the sensitivity of σ_f to P. Studies have reported this sensitivity factor to range from .015 and .074 [66]. These experimental data give a b value of .02, between porous glass and alumina [66].

$$-\sigma_f = \sigma_o \text{Exp}[-bP] \quad \text{Equation 4}$$

Raster orientation defines the direction of inter-bead pores and fiber. This has been shown to greatly impact the physical properties of FDMed materials [38, 67]. In this context, the author studies the effect of adjusting the raster orientation from -45°/45 to 0° on the mechanical properties and reliability of SCFR-ABS. In the 0° degree orientation, all infill beads are pointed in the direction of tensile load. This strengthens the material by more efficiently transferring the load to the short carbon fibers that now run parallel to the tensile load, increasing the cross-sectional area, and the inter-bead pores have reduced stress concentration due to their orientation. As a result, the change in raster orientation from -45°/ 45° increased the TS by 42 % and increased the elastic modulus by 67 % (Table 4).

The 0° raster orientation in this study was $\sim 30\%$ lower than the 0° reported by Telknip et al. [19]. This is mainly due to the reduced fiber length $91 \pm 52 \mu m$ and $77 \pm 44 \mu m$ compared to the $\sim 250 \mu m$ and 23 vol. % porosity reported (Table 4). Extrusion out of the 0.6mm reduced the as-received filament from $117 \pm 65 \mu m$ to $91 \pm 52 \mu m$ (22 % reduction) and $148 \pm 76 \mu m$ to $77 \pm 44 \mu m$ (a 48 % decrease). The change in fiber length before and after extrusion is shown in Figure 10. The average fiber diameter is $\sim 6-8 \mu m$ based on x-ray CT analysis. The researchers calculate that the critical fiber length (l_c) ideally would be between 216 MPa and 576 MPa, according to $l_c = \frac{\sigma_{fiber} d}{2\tau_m}$ [68] by assuming the carbon fiber strength $\sigma_{fiber} = 2.16 GPa$ [69] and the fiber-matrix interface shear strength $\tau_m = 30 - 15 MPa$ [19]. Effective strengthening of ABS with short fibers requires lengths higher than l_c (i.e., higher in aspect ratio) [70]. For example, increasing the composite by a factor of 10 would strengthen it up to $\sim 95\%$ [71].

Figure 10. Fiber-length measurements after filament was dissolved in reagent grade acetone (a) and raw filament (c). Extruded filament (b and d). Adopted from O. Keles et. al. [37].

In order to quantify mechanical reliability, σ_f , TS , ϵ_f , ϵ_{TS} were analyzed using Weibull statistics. These data were plotted and fitted with a dotted line showing the Weibull distribution (Figure 11, Table 4). The slopes of these Weibull distributions fit; the Weibull modulus (m) quantifies the variation in test results. There was no meaningful difference in variation in σ_f and TS for orientation for all seven test populations. In other words, the σ_f and TS showed similar dependence on P and raster orientation (Figure 11). The lowest Weibull modulus for σ_f (m_{σ_f}) was with $P = 34$ vol % and $m_{\sigma_f} = 18$. This

data set deviates at higher fracture stresses. An argument could be made that for engineering design purposes, the two higher fracture points could be removed from the data set because variations into higher stress are inconsequential for design applications, and the variability may be misleading and decrease the feasibility of that infill parameter. When these two high-stress data points are removed from the $P = 34 \text{ vol } \%$, the Weibull moduli increases from $m_{\sigma_f} = 18$ to 23, which is nominal to the other infill percentages. The populations of Weibull moduli were as low as technical ceramics (Figure 12). These large m values mean there is a large scatter of σ_f and TS, a 22 % difference between the strongest and weakest samples in the $P = 13 \text{ vol } \%$.

Figure 11. Weibull distribution plot of a) fracture strength; b) tensile strength; c) nominal strain at break; d) strain at tensile strength for FDMed SCFR-ABS. M1 P = 53 vol. % Δ , P = 41 vol. % $\times$, P = 34 vol. % $\bigcirc$, P = 25 vol. % ∇ , P = 15 vol. % $\diamond$, for M2 P = 13 vol. % $\square$, and P = 23 vol. % $+$. Adopted from O. Keles et. al. [37].

Figure 12. Effect of porosity on the Weibull modulus FDMed-SCFR composites; Δ is for M1, $\blacktriangle$ is for material 2 at 100 % infill, and $\blacktriangledown$ is for M2 at 100 % infill in 0° raster orientation. Error bars correspond to a 90 % confidence interval. Yellow represents moduli of FDMed ABS built in different orientations [18]. Gray represents experimental moduli of various porous ceramics [72]. Blue represents simulated modulus of brittle porous materials [72]. Adopted from O. Keles et. al. [37].

The Weibull moduli for strain was lower than that of strength (Figure 12, Table 4).

The m_{ϵ_f} values for the dense specimens were 11 for M1 and 9 for M2. The strain values for M1 ranged from 2.7 % to 4.1 %, a 34 % difference. The m_{ϵ_f} increased with porosity within the range of $P = 25$ to 53 vol. %. Similarly, the m_{TS} decreased with increasing porosity from 15 to 53 vol. %.

The m values of composites were higher than porous ceramics (Figure 12). These results are comparable to those reported in chapter six; however, they are lower than

those reported in previous studies: 46 and 67 for dense ABS in XY raster orientation [18]. This suggests that the printer resolution, nozzle diameter, and heated chamber may be causes of loss in mechanical reliability.

Microstructural sources of mechanical variation with FDMed SCFR-ABS include the distribution of pore size-shape-position, distribution of position-orientation-length-diameter, and disruption of the inter-bead pores as a function of positional accuracy. The fracture behavior of FDMed composites depends on inter-bead pore distribution, pore-to-pore interaction, pore-to-fiber interaction, and fiber/matrix interactions. These defects are the source of distribution in ϵ_f and ϵ_{TS} . In this context, the decreasing m_{ϵ_f} and $m_{\epsilon_{TS}}$ with increasing porosity can be attributed to low number of beads in the high-porosity sample (Figure 6). For example, if a bead contains large pores, it is unable to transfer the load to neighboring beads. A defect of this nature will experience a catastrophic failure at lower strains than samples not containing a larger pore. Samples with many neighboring beads (low P samples) have a narrow distribution of ϵ_f and, therefore, a higher Weibull modulus.

The effect of bead orientation and raster-to-contour inter-bead pores was studied with tensile tests on 0° degree bead-orientation samples. Comparing the 45°/-45° to 0° bead orientation nearly doubled all Weibull moduli for σ_f , TS , ϵ_f , and ϵ_{TS} (Table 4). There is also a ~25 % higher strength and a 66 % increase in elastic modulus compared to the 45°/-45° orientation (Table 4). A large batch-to-batch variance was seen in the 0° samples. These samples are printed in batches of 10; the first two batches exhibited an average σ_f of ~30.5 MPa, while the last batch showed an average of 37 MPa. This last, higher

σ_f batch is shown by the upper-tail deviation seen in Figure 11. The author disregarded these 10 samples in order to avoid underestimating the true m value. The higher m_{σ_f} of the 0° bead orientation, compared to $45^\circ/-45^\circ$ bead orientation, demonstrates the effect of fiber, inner-bead, and inter-bead orientation on variability.

The mechanical properties and reliability were also studied for the as-received filament and extruded filament (Figure 13). The fracture surfaces of the as-received filament and extruded filament are shown in Figures 7c and 7e. The orientation of the fibers makes it very similar to the 0° bead orientation specimens. The m_{σ_f} of the as-received filament was 62 and 27 for M1 and M2, respectively. This shows that the reliability of the 0° bead orientation can be as high for Weibull moduli for the as-received filament. The extruded filament showed a m_{σ_f} of 23, which is statistically the same as the dense specimens with $45^\circ/-45^\circ$ bead orientation. The decrease in Weibull modulus after extrusion indicates the production of defects, such as increased porosity and decreasing fiber length (Figure 13).

Figure 13. Weibull distribution for fracture stress of the extruded filament ($\bigcirc$), M1 filament ($\times$), and M2 filament ($\diamond$) Adopted from O. Keles et. al. [37].

The Anderson Darling and Pearson χ^2 goodness-of-fit-tests were used to determine if these data fit a Weibull or normal distribution. The P-values of these tests did not indicate a preference between the Weibull and normal distributions. In order to determine a bias, a larger sample size is needed. The mechanical properties did deviate from the Weibull distribution. The origin of these deviations is difficult to isolate in a complex case of interactions of different-sized pores [38], fibers, and lattice structures.

Although the exact failure mechanisms were not proven, the researchers believe that the variations in size of the inter-bead and inner-bead pores caused scatter in mechanical properties. Variations in inter-bead porosity depend on the extrusion bead thickness and the accuracy and precision of the heated extruder. Factors that affect the extrusion bead thickness include fiber content, filament diameter, and porosity of as-received filament.

Variations in these properties cause variations in the size and shape of inter-bead pores and are believed to vary the mechanical properties of the FDMed part.

Irregularities in extruded bead thickness are mostly properties of the as-received filament; however, irregularities in deposition accuracy and precision are functions of the FDM itself. The precision of this system is limited by stepper motors and a belt-driven system; beads can be deposited closer to or farther away from a desired location to a neighboring bead. Porosity in the feedstock not only contributes to bead thickness (and therefore inter-bead porosity), but it also affects the variations in inner-bead porosity.

Differences in the mechanical behavior of M1 and M2 were observed. M1 and M2 were sold as the same filament yet advertised improvements to the filament. The M2 as-received filament was ~17 % stronger than M1 but was 22 % less ductile. This shows that differences in feedstock material have a noticeable effect on mechanical properties. Therefore, a homogeneous filament is needed to achieve high mechanical reliability.

6.4 Conclusion

This paper reports the mechanical properties and variability of FDMed SCFR ABS as a function of porosity. The effect of raster orientation on mechanical properties was also examined. With high-resolution X-ray μ CT, five distinct pores are identified: pores generated by the infill parameter, inter-bead pores, inner-bead pores due to fiber-matrix mismatch, inner-bead pores in as received feedstock, and pores generated from extrusion.

The fracture strength of the FDMed SCFR-ABS decreased with increasing porosity at a rate of $\sigma_f = 30Exp[-0.02P]$ for $13 < P < 53$ % by volume. The Weibull modulus for ϵ_f and ϵ_{TS} decreased with increasing porosity from 25 to 53 vol. %. By switching the

raster orientation from 45/-45 to 0°, the author showed an increase of the Weibull modulus for σ_f , TS , ϵ_f , and ϵ_{TS} and an increase in the average σ_f by ~40 %. Extruding the 1.75 mm diameter filament from the .6 mm nozzle decreased the carbon-fiber length from 22 % to 48 %.

The researchers believe that one major cause of mechanical variability is the low accuracy of the printer, causing higher variability in inter-bead porosity. Higher-resolution printers may be able to produce prints with lower variability in inter-bead porosity. A pore-free filament will produce more uniform inter-bead pore distributions, improving reliability. Finally, a longer fiber and stronger matrix adhesion can be achieved, causing increased mechanical reliability.

CHAPTER SEVEN

MECHANICAL RELIABILITY OF SHORT CARBON FIBER REINFORCES ABS PRODUCED VIA VIBRATION ASSISTED FUSED DEPOSITION MODELING

As shown in the previous chapter, FDMed SCFR-ABS has significant room for improvement in reliability and tensile properties. As discussed in Tekinalp et al. [19], inter-bead porosity is an air pocket in between two extruded beads that the composite material was unable to fill. These triangular-shaped pore regions can act as stress concentrators and can reduce the mechanical properties of the FDM part [38]. In this chapter, a novel vibration-assisted FDM process is introduced for decreasing the inter-bead porosity and therefore increasing the mechanical properties of the SCRF-ABS.

Twenty-four vibrated samples were printed with identical processing parameters to the 100 % infill samples in the previous chapter. The 100 % infill new-material data were used as the non-vibrated control for this experiment. As in previous sections, a Weibull analysis was used to quantify variations in fracture stress, tensile stress, tensile strain, and fracture strain.

Via SEM imaging, a clear reduction in inter-bead porosity was observed over non-vibrated samples. This had the desired effect of increasing all measured mechanical properties, including a 100 % improvement in mechanical reliability. These results introduce a low-cost manner of increasing the density of FDM parts, increasing their relevant applications and therefore driving the industry. These results also offer statistical data, useful as a design guideline for predicating failure rates.

7.1 Introduction

Inter-bead porosity has been correlated to reduced mechanical properties and reliability [18, 19]. Reducing this inter-bead porosity would have significant effects on the mechanical properties and reliability; however, creating a non-inter-bead FDM part is difficult [18, 19, 52]. To address the inter-bead porosity, Qiu and Langrana et al. numerically show a reduction in inter-bead porosity via an algorithm extrusion [62]. Wang et al. used expanding microspheres to reduce the inter-bead porosity in post-processing [63]. Although these two techniques have proven successful at reducing inter-bead porosity, they are effective with only smaller nozzle sizes; therefore, these techniques are not useful for composite parts. Composite filament must be printed using an FDM nozzle larger than 0.5 mm to avoid clogging [19]. These larger nozzles producing larger inter-bead pores cannot currently be eliminated using algorithms, microspheres, or any post-processing technique.

In this paper, the author presents a novel, cost-effective way of reducing inter-bead porosity of a 0.6 mm nozzle FDM printer and calls this new method the “vibration-assisted fused deposition modeling” (VA-FDM). This technique is different than the recent ultrasonic vibration-based technique, which focuses on surface finish [73]. The researchers also present the mechanical properties and reliability for this work, which can be used to aid design to make safer and higher specific stress parts. Finally, the researchers speak to the origins of variations in mechanical reliability.

7.2 Materials and Method

Please see chapter 4.1.1 for all modeling descriptions; 4.1.2 for fractography descriptions; 4.1.3 for the tensile testing description; 4.1.4 for the Weibull analysis description; and 4.1.5 for the tensile dog-bone printing description. Differences in the methods from previous experiments are described below.

This study was to determine the mechanical properties with tensile test specimens printed with and without vibration. To achieve vibration, a 12-V direct-current vibrational motor with an offset 30-g mass was attached to the heat sink of the extrusion head. The motor was connected to the FDM system in the standard fan location. This provides the advantage of turning the vibrational motor on or off with G-code, using standard fan commands (M106 S40 and M107, respectively). This provided control, allowing vibration only on the infill portions of layers 3 through 10 out of the 12. Because the vibrational motor was now connected to the standard fan pins, the fan was relocated to an (always on) 5-V pin on the Arduino board. The resulting vibrational amplitude was ~.15 mm peak to peak. The vibrational wavelength was 4.8 mm at ~ 375 Hz and 2400 mm/min. The actual wavelength should be lower because of the velocity changes of the print heads during print.

A total of 47 non-vibrated specimens and 37 vibrated specimens were printed. Out of these tests, 23 of each population were valid due to fractures in the tensile test grips. Fracture stress and strain at fracture was determined only using the valid 23 samples; however, tensile strength and strain at tensile strength was reported with all printed samples.

7.3 Results and Discussion

With the addition of vibrations to the FDM process, the SEM of the fracture surface shows a decrease in porosity (Figure 14). This is confirmed with density measurements, showing a reduction in total percent porosity from 13 % to 10 %. Additional to the reduction of inter-bead pore size, a change in bead morphology is also seen. Long-channeled, triangulated pores (Figures 14b2 and 14b3) become a zigzagging pattern with the potential to terminate channels against the neighboring raster (Figures 14c2 and 14c3]. The inter-bead porosity is changed by the vibrating head physically pushing the low viscosity material on an already-deposited bead.

Figure 14. a) Schematic of the relative positions of the vibrational motor, extrusion head, and cooling fan, respectively; b) Depiction of the inter-bead porosity generated by the standard fused deposition modeled method; c) Depiction of the inter-bead pore generation from vibrational fused deposition modeled. Adopted from O. Keles et. al. [38]

Inner-bead porosity was seen in both the FDM and VA-FDM samples. Inner-bead porosity has been reported to be caused by both the viscosity incompatibility between the fiber and ABS plastic, as well as the temperature of the nozzle [19, 52]. A nozzle

extrusion temperature of 235° C—the temperature used in this study—has been shown to introduce inner-bead porosity. The extent of pore generation is unknown, due to being dependent on fiber concentration. In addition to this the feedstock was at 5 % as received, as reported by X-ray μ CT in Chapter 7.

Inter-bead porosity is the largest and highest stress concentrator in FDMed composites. Tekinalp et al. reported higher mechanical properties for compression molded SCFR-ABS, with no inter-bead porosity, than FDMed SCFR-ABS. Similarly, as inter-bead porosity was reduced via vibrations, fracture strength (σ_f), tensile strength (TS), and nominal strain at break (e_f) increased by more than 10 %. The elastic modulus was also increased from 2.5 ± 0.1 GPa to 2.7 ± 0.1 GPa. This increase can be seen in Figure 15. The stress-strain curves for the vibrated and non-vibrated populations are shown in Figure 16.

Figure 15. Linearized Weibull distribution for non-vibrated (blue circle) and vibrated (red x) FDMed SCFR-ABS. m_v , $\sigma_{0,v}$, m_{nv} , and $\sigma_{0,nv}$ are vibrated Weibull modulus, vibrated characteristic value, non-vibrated modulus, and non-vibrated characteristic value. a) Fracture stress; b) tensile strength; c) nominal strain at break; d) strain at tensile strength. Adopted from O. Keles et. al. [38].

Figure 16. Stress-strain curves of the highest fracture stress of the vibrated and non-vibrated populations. Adopted from O. Keles et. al. [38].

Weibull analysis was used to quantify the variations in σ_f , TS , e_f and strain at TS (e_{TS}). The Weibull modulus showed an increase with vibrated for TS and σ_f by 200 %. This means the variance in σ_f , TS and e_f is much less than with the vibrated samples. Previous work with clean ABS showed a significantly higher modulus ($m = 46$) than the non-vibrated ($m = 25$). With vibrations, the modulus increased from 25 to 57. This is higher than the previous $m = 46$ clean ABS produced by the Stratasys uPrint SE. This suggest that a low-cost printer is capable of producing parts as, or more, reliable than the high-end Stratsys system. Vibrations decreased the e_{TS} , showing that the maximum load-bearing capacity is reached at lower strain levels than non-vibrated. This means that the vibrated specimen has a more uniform microstructure than the non-vibrated. Additionally, an Anderson-Darling goodness-of-fit test was used to determine whether

the data represent a normal or Weibull distribution. There was no significant statistical difference between the Weibull and normal distributions.

An improved Weibull modulus means a more reliable material; low allowable-failure-rate materials with low Weibull moduli are unusable. Therefore, any improvements to the Weibull modulus increases the possibility of FDMed for manufacturing applications.

The variation in mechanical properties is primarily determined by the size and morphology of the inter-bead pores. The consistency of the size and shape of these inter-bead pores is dependent on the accuracy of the printer. If the printer can lay beads at a consistent distance from each other, the inter-bead pores will be consistent. However, if the accuracy of the printer is low, then the bead-to-bead spacing will differ, varying the sizes and shapes of the inter-bead pores. Mechanical factors affecting accuracy include the extrusion-nozzle diameter, servo motors, and the belt system. There are also factors that contribute to the inter-bead pore size that are not native to the printer: filament homogeneity, variations in filament thickness, and G-code variations.

The mechanical properties of FDMed SCFR-ABS depend on inter-bead pores, inner-bead pores, carbon fiber, crazing, and their interactions. Of these features, inter-bead pores have the largest effect on mechanical properties. This is due to the size and stress concentration they add to the system. This effect can be seen when comparing the fracture surfaces of vibrated and non-vibrated material (Figure 17). The non-vibrated specimen has a single crazing region (seen as cloudy white on the fracture surface), whereas the vibrated has two less-concentrated crazing regions. These multiple crazing regions indicate competing crack propagation. This shows that the reduced vibrated

samples distribute the load more evenly through the sample than the large pores of the non-vibrated material.

Figure 17. Photographs of the surface finish of the vibrated and non-vibrated tensile-test specimens. Adopted from O. Keles et. al. [38].

In both the vibrated and non-vibrated samples, the fracture originates from the inter-bead pores near the contour. The vibrated specimens narrow the distribution of pore sizes by eliminating elongated pores. With a narrow distribution of inter-bead pore sizes, the distribution of mechanical properties also becomes narrower.

One possible concern of adding a vibration to the print process is the effect on build resolution. To mitigate this, the perimeter, the top two layers, and the bottom two layers were not vibrated. A difference in surface roughness can be seen on the top and side surface of the part (Figure 17). This can be mitigated by more non-vibrated surface layers and more parameters. Generally, specimens were thicker and wider compared to those that were non-vibrated. The height was $3.88 \pm .05 \text{ mm}$ average for non-vibrated and $3.93 \pm 0.1 \text{ mm}$ average vibrated. The width was $13.2 \pm 0.1 \text{ mm}$ average for non-vibrated and $13.3 \pm .2 \text{ mm}$ average for vibrated.

VA-FDM is a novel, cost-effective technique for reducing inter-bead porosity and therefore improving the mechanical properties of the SCFR-ABS. By attaching the vibrational motor to the fan's pulse-width modulated pins on the Arduino board, the vibrations can be turned on and off, and frequency can be adjusted at will. This gives the ability to preserve surface finish and optimize vibration frequency for different head-travel speeds and nozzle diameters. With the addition of vibrational motors in different axes and an ultrasonic transducer, the researchers believe that further reductions in porosity can be achieved. The researchers also believe that this technique can reduce the size and number of inner-bead pores, allowing for larger nozzle diameters and faster print with stronger materials.

7.4 Conclusion

The mechanical properties of FDMed composites are major barriers for widespread adoption in mass-production and mass-customization industries. The novel technique presented in this paper, VA-FDM, has been shown to decrease inter-bead porosity. Decreasing the inter-bead porosity increased fracture strength, tensile strength, nominal strain at break, and the elastic modulus of FDMed SCFR-ABS. The work of fracture also increased by 49 %. The variations in mechanical properties were decreased; in other words, the mechanical reliability of the material was increased. VA-FDM nearly doubled the Weibull moduli of σ_f and TS. Further improvements on mechanical properties can be achieved by reducing infill to contour pores, increasing contour thickness, and using pore-free filaments.

CHAPTER EIGHT

CONCLUSION AND FUTURE WORK

This paper aims to accomplish three goals: first, to provide reliability data for consumer-based FDMed ABS and SCFR-ABS; second, to investigate the causes of low mechanical properties; and finally, to address identified causes of mechanical variations and improve mechanical properties and reliability. A summary and future work will be discussed below.

8.1 Reliability Data

In this paper, the author reported the mechanical properties and reliability as a function of porosity in Tables 3 and 4, for neat ABS and SCFR-ABS, respectively. In addition to data that have been produced by this research group, there have not been sample sizes large enough to conduct adequate reliability studies for FDMed polymers and composites. Additive manufactured parts should be used for load-bearing applications to maintain commercial growth. Without reliability data, parts may be produced with improper processing parameters, risking property and human safety. The author believes that these data would best be utilized by slicing software. Designers would specify forces on their desired parts as well as acceptable failure rates; then, the software would suggest the infill percentage that would optimize performance, speed, and material usage.

There are many production parameters that could affect the reliability of FDMed materials. Nozzle diameter, extrusion temperature, and material selection are all parameters suggested to affect mechanical reliability, but these were out of the scope of this thesis. The only studies conducted in this work involved tensile forces. There are

missing reliability data for other mechanical tests, including four-point bend tests, cycle testing, and high-strain studies. For a robust parameter-selecting, slicing software, these additional data sets would be beneficial.

8.2 Investigating the Causes of High Variance

The nominally dense material reported in this study was 15, 13, 23, 10, and 8 vol. % for SCFR-ABS M1, SCFR-ABS M2, SCFR-ABS M2 0°, SCFR-ABS M2 vibrated and neat ABS, respectively (Table 5). These porous samples dominate the mechanical variability behavior. Pores in FDMed polymers and composites come in two varieties: inner-bead and inter-bead pores. In chapter 6.3, the author discussed the factors that may contribute to the production of inner- and inter-bead pores. Factors that contribute to inter-bead porosity include carbon-fiber content, printer positional accuracy, and nozzle diameter. Factors that contribute to inner-bead porosity are fiber-matrix mismatch, porosity in feedstock filament, and extrusion temperature.

Table 5 Porosity of Nominally Dense FDMed Material

Approximate Vol. % of Pores	Description
15	SCFR-ABS M1
13	SCFR-ABS M2
23	SCFR-ABS M2 0°
10	SCFR-ABS M2 vibrated
8	neat ABS

With the vibrated-assisted FDM printing, the researchers were able to show that a reduction in porosity corresponds to a reduction in mechanical variability. However, the degree to which each pore type contributed to mechanical reliability is unknown. Future

work could include testing the pore-generating parameters to examine their contribution to mechanical reliability. For example, the effect of extrusion temperature on inter- and inner-bead formation and mechanical reliability would be a useful study.

8.3 Addressing Identified Causes of Mechanical Variability

The inner- and inter-bead pores were identified in chapter six. To address these properties, vibrational-assisted FDM was developed in order to reduce these pores in hopes of increasing mechanical properties. The average porosity of the tensile specimen was 8 vol. % compared to 13 vol. % of the non-vibrated. This is evidence of a reduction of inner- and inter-bead pores. Fracture stress, tensile strength, and strain at fracture all increased by 10 %. The Weibull modulus for fracture stress increased 200 %. This suggests that there is a strong correlation between porosity and mechanical reliability.

The vibrational method reduced porosity but did not isolate between inter- and inner-bead porosity. Future research would investigate the degree of pore reduction for both inter- and inner-bead reduction as well as of fiber orientations that would contribute to strengthening and improvement in reliability. Further improvements could be made to improve the mechanical properties of FDMed SCFR ABS. The improvements actively pursued by this group include multi-axis vibrations, feedback-vibration systems, and ultrasonic tip vibrations. In addition to this, other systems including clean ABS, lower infill percentages, and other FDM machines could further the understanding of this process.
